

An Overview of Tensor Decompositions in Wireless Communications and MIMO Radar

Hongyang Chen, *Senior Member, IEEE*, Fauzia Ahmad, *Fellow, IEEE*, Sergiy Vorobyov, *Fellow, IEEE*,
and Fatih Porikli, *Fellow, IEEE*,

Abstract—The emergence of big data and the multidimensional nature of wireless communication signals present significant opportunities for exploiting the versatility of tensor decompositions in associated data analysis and signal processing. The uniqueness of tensor decompositions, unlike matrix-based methods, can be guaranteed under very mild and natural conditions. Harnessing the power of multilinear algebra through tensor analysis in wireless signal processing, channel modeling, and parametric channel estimation provides greater flexibility in the choice of constraints on data properties and permits extraction of more general latent data components than matrix-based methods. Tensor analysis has also found applications in Multiple-Input Multiple-Output (MIMO) radar because of its ability to exploit the inherent higher-dimensional signal structures therein. In this paper, we provide a broad overview of tensor analysis in wireless communications and MIMO radar. More specifically, we cover topics including basic tensor operations, common tensor decompositions via canonical polyadic and Tucker factorization models, wireless communications applications ranging from blind symbol recovery to channel parameter estimation, and transmit beamspace design and target parameter estimation in MIMO radar.

Index Terms—Tensor decomposition, tensor factorization, rank, parallel factor analysis (PARAFAC), Tucker model, CDMA, MIMO, symbol recovery, millimeter wave, transmit beamspace, radar.

I. INTRODUCTION

A tensor is a multidimensional array. A first-order tensor is a vector, a second-order tensor is a matrix, and tensors of order three or higher are generalized matrices called higher-order tensors. An N th-order tensor is an element of the tensor product of N vector spaces [1]–[5]. Tensor algebra is generalized from matrix algebra. Thus, the two have many similarities, but at the same time, they also have different properties. Higher-order tensors and their decompositions have recently become pervasive in signal processing, data analytics, and machine learning.

The roots of multiway data analysis can be traced back to studies of homogeneous polynomials by Hitchcock in the late 1920s [6], [7], followed by other contributions including those by Tucker [8]–[10], Carroll and Chang [11], and Harshman [12]. The Tucker decomposition for tensors was

introduced in psychometrics [9], [10], while the canonical polyadic decomposition (CPD) was independently discovered and put in an application context under the names of canonical decomposition (CANDECOMP) in psychometrics [11] and parallel factor model (PARAFAC) in linguistics [12]. Besides the developments in psychometrics, tensor decompositions have been examined and applied in other fields, such as chemometrics, the food industry, social sciences [13], [14], and signal processing [15]–[17].

With regard to signal processing in wireless communications, the received signal is multidimensional in nature and may exhibit a multilinear algebraic structure [18]. However, owing to the broad system variety with differing yet complex transmission structures, realistic channel models, and efficient receiver signal processing, wireless communications offer new challenges for applying tensor decompositions. A high-speed wireless transmission is impacted by various factors in the physical layer, such as interference from different sources, attenuation of signal power with distance, and other signal fading effects of the wireless communication channel. At the receiver, signal processing is generally used to combat multipath fading effects, inter-symbol interference (ISI), and multiuser (co-channel) interference by means of multiple receive antennas. Wireless communication systems employing multiple antennas at both ends of the link, commonly known as Multiple-Input Multiple-Output (MIMO) systems, are being considered as one of the key technologies to be deployed in current and upcoming wireless communications standards [19]. Generalized tensor decompositions are typically required to cover the disparate communication system types. Besides, tensor decompositions can also be used to address multi-antenna array processing problems, such as blind spatial signature estimation [20]. The tensor approach can ease restrictive assumptions which are required by many conventional approaches.

In [21]–[23], the authors examined the integration of multiple-antenna and Code-Division Multiple-Access (CDMA) technologies. As described in [24]–[26], tensor modeling based MIMO systems have been demonstrated to potentially provide high spectral efficiencies by capitalizing on spatial and code multiplexing. Furthermore, for a third-order received signal tensor, each signal sample is an element of a three-dimensional (3-D) tensor and is represented by three indices, each associated with a specific type of systematic variation of the received signal. In such 3-D space, each dimension of the received signal tensor can be interpreted as a particular form of signal “diversity”. In most cases, two

of the three dimensions account for space and time. The third dimension, however, depends on the specific wireless communication system considered. For instance, the third dimension can correspond to frequency in MIMO Orthogonal Frequency Division Multiplexing (MIMO-OFDM) system [27]. By means of Space-Time-Frequency (STF) coding [28]–[31], the MIMO-OFDM communication systems are able to achieve high data rates and combat fading effects [32]–[37]. In [38]–[44], the authors investigated cooperative relay-assisted MIMO communications, which have emerged as a popular means for enhanced wireless system performance, improved quality of service, and cost and structure reduction. Tensor-based approaches have gained considerable attention in cooperative MIMO communication systems.

MIMO radar technology has garnered substantial research interest over the last decade and has found applications in over-the-horizon radar, maritime radar, automotive radar, and dual-function radar-communications, to name a few [45]–[56]. A MIMO radar with multiple colocated transmit and receive antennas can estimate target parameters of interest through simultaneous transmission of several orthogonal waveforms and coherent processing of the radar returns. Although the antennas constituting the transmit array or the receive array are closely spaced, the arrays themselves may not be colocated, as is the case in bistatic MIMO radar. The configuration with colocated transmit and receive arrays, on the other hand, is called a monostatic MIMO radar. Proper exploitation of waveform diversity and degrees-of-freedom offered by the multi-antenna transmit/receive configurations for interference suppression and resolution enhancement can lead to improvements in target detection and parameter estimation performance over a conventional radar. Similar to wireless communications, MIMO radar signal processing can benefit from tensor analysis in successfully achieving reliable and effective target parameter estimation [57]–[61].

The main purpose of this paper is to provide a comprehensive overview of tensor decompositions in the application areas of wireless communications and MIMO radar. Towards this objective, in Section II, we review some basic tensor operations and common tensor decompositions, including Tucker and CPD. The uniqueness of the decompositions is also briefly discussed. Section III provides a detailed survey of tensor analysis in wireless communications, ranging from blind symbol recovery to time-varying channel modeling and parameter estimation for different systems, including multiuser CDMA, cooperative/relay systems, and millimeter wave (mmWave) communication systems. In Section IV, we present an overview of tensor-based methods in MIMO radar, focusing on target localization and transmit beamspace (TB) design. Section V provides conclusions. It is noted that the topics and related research that we have showcased in this paper are by no means exhaustive. Rather, they inform the reader about the type of opportunities present in the considered application areas for employing tensor algebra and decompositions.

Notation: Scalars, column vectors, matrices, and tensors are denoted by lowercase, boldface lowercase, boldface uppercase, and calligraphic uppercase letters, such as a , \mathbf{a} , \mathbf{A} and \mathcal{A} , respectively. The vector \mathbf{a}_i (resp. \mathbf{a}_j) represents the i th row

(resp. j th column) of matrix \mathbf{A} . The operations \mathbf{A}^T , \mathbf{A}^* , \mathbf{A}^H , \mathbf{A}^{-1} , and $r_{\mathbf{A}}$ denote the transpose, the conjugate, the conjugate (Hermitian) transpose, the Moore-Penrose pseudo-inverse, and the rank of \mathbf{A} , respectively. The operator $D_i(\cdot)$ forms a diagonal matrix from the elements of the i th row of its matrix argument. The symbols \circ , \otimes , \odot , and \diamond represent outer product, Kronecker product, Hadamard (element-wise) product, and Khatri-Rao product, respectively. The remaining notation should be clear from the context.

II. BASIC TENSOR OPERATIONS AND DECOMPOSITIONS

In this section, we review some useful matrix products, basic tensor operations, and common tensor decompositions [62]–[65]. These establish the preliminaries for the application-specific descriptions that follow in subsequent sections.

A. Basic Definitions and Operations

Definition 1. *Kronecker product of two matrices:* The Kronecker product of $\mathbf{A} \in \mathbb{C}^{I \times J}$ and $\mathbf{B} \in \mathbb{C}^{M \times N}$ is defined as

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{1,1}\mathbf{B} & a_{1,2}\mathbf{B} & \cdots & a_{1,J}\mathbf{B} \\ a_{2,1}\mathbf{B} & a_{2,2}\mathbf{B} & \cdots & a_{2,J}\mathbf{B} \\ \vdots & \vdots & \ddots & \vdots \\ a_{I,1}\mathbf{B} & a_{I,2}\mathbf{B} & \cdots & a_{I,J}\mathbf{B} \end{bmatrix} \in \mathbb{C}^{IM \times JN}. \quad (1)$$

Considering additional matrices $\mathbf{C} \in \mathbb{C}^{J \times P}$, $\mathbf{D} \in \mathbb{C}^{Q \times P}$, and $\mathbf{E} \in \mathbb{C}^{Q \times M}$, we have the following properties:

Property 1.

$$\text{vec}(\mathbf{ACD}^T) = (\mathbf{D} \otimes \mathbf{A}) \text{vec}(\mathbf{C}) \in \mathbb{C}^{IQ}. \quad (2)$$

where $\text{vec}(\cdot)$ denotes columnwise vectorization of its matrix argument.

Property 2.

$$(\mathbf{A} \otimes \mathbf{E})(\mathbf{C} \otimes \mathbf{B}) = (\mathbf{AC}) \otimes (\mathbf{EB}) \in \mathbb{C}^{IQ \times PN}. \quad (3)$$

Definition 2. *Khatri-Rao product of two matrices:* The Khatri-Rao product of $\mathbf{A} \in \mathbb{C}^{M \times J}$ and $\mathbf{B} \in \mathbb{C}^{N \times J}$ is defined as the column-wise Kronecker product,

$$\mathbf{A} \diamond \mathbf{B} = [\mathbf{a}_1 \otimes \mathbf{b}_1 \quad \mathbf{a}_2 \otimes \mathbf{b}_2 \quad \cdots \quad \mathbf{a}_J \otimes \mathbf{b}_J] \in \mathbb{C}^{MN \times J}. \quad (4)$$

The Khatri-Rao product $\mathbf{A} \diamond \mathbf{B}$ can also be calculated as

$$\mathbf{A} \diamond \mathbf{B} = \begin{bmatrix} \mathbf{BD}_1(\mathbf{A}) \\ \vdots \\ \mathbf{BD}_I(\mathbf{A}) \end{bmatrix}. \quad (5)$$

Definition 3. *Inner product of two tensors:* The inner product of two tensors $\mathcal{A} \in \mathbb{C}^{I_1 \times \cdots \times I_M}$ and $\mathcal{B} \in \mathbb{C}^{I_1 \times \cdots \times I_M}$ of the same order M is defined as

$$\langle \mathcal{A}, \mathcal{B} \rangle = \sum_{i_1=1}^{I_1} \sum_{i_2=1}^{I_2} \cdots \sum_{i_M=1}^{I_M} a_{i_1, i_2, \dots, i_M} b_{i_1, i_2, \dots, i_M}. \quad (6)$$

Definition 4. *Outer product of two tensors:* The outer product of an M th order tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times \cdots \times I_M}$ and an N th

order tensor $\mathcal{B} \in \mathbb{C}^{J_1 \times \dots \times J_N}$ is defined as the $(M + N)$ th order tensor $\mathcal{A} \circ \mathcal{B}$ with elements

$$(\mathcal{A} \circ \mathcal{B})_{i_1, i_2, \dots, i_M, j_1, j_2, \dots, j_N} = a_{i_1, i_2, \dots, i_M} b_{j_1, j_2, \dots, j_N}. \quad (7)$$

Definition 5. Mode- n product of a tensor and a matrix: Consider a tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times \dots \times I_N}$ and a matrix $\mathbf{X} \in \mathbb{C}^{L \times I_n}$, with I_n equal to the dimension of the n th mode of \mathcal{A} . The mode- n product between the tensor \mathcal{A} and the matrix \mathbf{X} yields an N th order tensor $\mathcal{B} = \mathcal{A} \times_n \mathbf{X} \in \mathbb{C}^{I_1 \times \dots \times I_{n-1} \times L \times I_{n+1} \times \dots \times I_N}$ such that

$$b_{i_1, \dots, i_{n-1}, l, i_{n+1}, \dots, i_N} = \sum_{i_n=1}^{I_n} a_{i_1, \dots, i_{n-1}, i_n, i_{n+1}, \dots, i_N} x_{l, i_n}. \quad (8)$$

Definition 6. Rank-one tensor: The tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times \dots \times I_M}$ is said to be a rank-one tensor if it can be expressed as the outer product of M vectors $\mathbf{v}_m \in \mathbb{C}^{I_m}$, with $m \in [1, M]$ as

$$\mathcal{A} = \mathbf{v}_1 \circ \mathbf{v}_2 \cdots \circ \mathbf{v}_M. \quad (9)$$

The entries of \mathcal{A} can be presented as $a_{i_1, i_2, \dots, i_M} = v_1^{(i_1)} \cdots v_M^{(i_M)}$. Fig. 1 illustrates a rank-one tensor of order 3, represented as the outer product of vectors \mathbf{a} , \mathbf{b} , and \mathbf{c} .

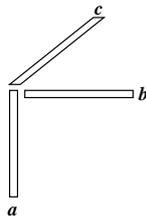

Fig. 1. Schematic of a rank-one tensor of order 3.

Definition 7. The rank of a tensor: The rank $r_{\mathcal{A}}$ of tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times \dots \times I_M}$ is defined as the minimal number of rank-one tensors that combine linearly to generate \mathcal{A} . Fig. 2 presents a 3-way tensor of rank three.

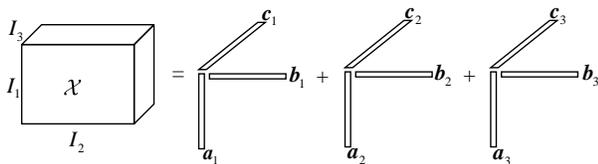

Fig. 2. Schematic of a 3-way tensor of rank 3.

Definition 8. k -rank: The rank $r_{\mathbf{A}}$ of $\mathbf{A} \in \mathbb{C}^{I \times J}$ is equal to r if \mathbf{A} contains at least a set of r linearly independent columns but no set of $r+1$ linearly independent columns. The Kruskal-rank (or k -rank) of \mathbf{A} is the maximum number k such that every set of k columns of \mathbf{A} is linearly independent. Note that the k -rank is always less than or equal to $r_{\mathbf{A}}$. That is,

$$k_{\mathbf{A}} \leq r_{\mathbf{A}} \leq \min(I, J). \quad (10)$$

B. Tensor Decompositions

1) *Tucker decomposition:* The Tucker decomposition decomposes a tensor into a core tensor of the same order

and some factor matrices. For an M th order tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times \dots \times I_M}$, the Tucker decomposition is defined as [10]

$$\mathcal{A} = \mathcal{Q} \times_1 \mathbf{X}^{(1)} \times_2 \mathbf{X}^{(2)} \cdots \times_M \mathbf{X}^{(M)}, \quad (11)$$

where $\mathcal{Q} \in \mathbb{C}^{J_1 \times \dots \times J_M}$ is the core tensor and $\mathbf{X}^{(m)} \in \mathbb{C}^{I_m \times J_m}$, with $m = 1, \dots, M$, are the factor matrices. The elements of \mathcal{A} can be represented as

$$a_{i_1, \dots, i_M} = \sum_{j_1=1}^{J_1} \cdots \sum_{j_M=1}^{J_M} q_{j_1, \dots, j_M} \prod_{m=1}^M x_{i_m, j_m}^{(m)}. \quad (12)$$

For illustration, we show in Fig. 3 the Tucker decomposition of a third-order tensor $\mathcal{X} \in \mathbb{C}^{I_1 \times I_2 \times I_3}$ as $\mathcal{X} = \mathcal{Q} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}$, where $\mathcal{Q} \in \mathbb{C}^{J_1 \times J_2 \times J_3}$ is the core tensor and the factor matrices are denoted by $\mathbf{A} \in \mathbb{C}^{I_1 \times J_1}$, $\mathbf{B} \in \mathbb{C}^{I_2 \times J_2}$ and $\mathbf{C} \in \mathbb{C}^{I_3 \times J_3}$.

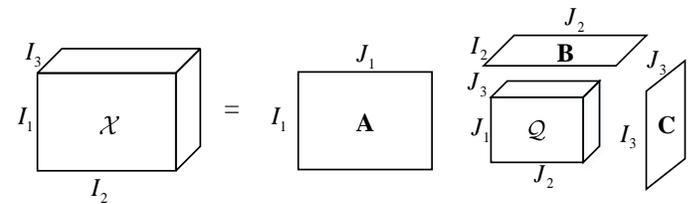

Fig. 3. Block-diagram of a Tucker decomposition for a third-order tensor.

2) *PARAFAC/CPD:* The PARAFAC decomposition, also known as CANDECOMP or CPD, represents a tensor as a linear combination of a minimum number of rank-one tensors [12]. For an M th order tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times \dots \times I_M}$, the PARAFAC decomposition is expressed as

$$\mathcal{A} = \sum_{r=1}^R \mathbf{x}_r^{(1)} \circ \mathbf{x}_r^{(2)} \circ \dots \circ \mathbf{x}_r^{(M)}, \quad (13)$$

where $\mathbf{x}_r^{(m)} \in \mathbb{C}^{I_m}$ is the r th column vector of factor matrix $\mathbf{X}^{(m)} \in \mathbb{C}^{I_m \times R}$. The PARAFAC model can also be represented in scalar form as

$$a_{i_1, \dots, i_M} = \sum_{r=1}^R \prod_{m=1}^M x_{i_m, r}^{(m)}. \quad (14)$$

Consider a third-order tensor $\mathcal{X} \in \mathbb{C}^{I_1 \times I_2 \times I_3}$, whose PARAFAC decomposition $\mathcal{X} = \sum_{r=1}^R \mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r$ with $\mathbf{A} \in \mathbb{C}^{I_1 \times R}$, $\mathbf{B} \in \mathbb{C}^{I_2 \times R}$ and $\mathbf{C} \in \mathbb{C}^{I_3 \times R}$. We can obtain the following matrix slices as

$$\mathbf{X}_{i_1, :, :} = \sum_{r=1}^R a_{i_1, r} \mathbf{b}_r \mathbf{c}_r^T = \mathbf{B} \mathbf{D}_{i_1}(\mathbf{A}) \mathbf{C}^T \in \mathbb{C}^{I_2 \times I_3}, \quad (15)$$

$$\mathbf{X}_{:, i_2, :} = \sum_{r=1}^R b_{i_2, r} \mathbf{c}_r \mathbf{a}_r^T = \mathbf{C} \mathbf{D}_{i_2}(\mathbf{B}) \mathbf{A}^T \in \mathbb{C}^{I_3 \times I_1}, \quad (16)$$

$$\mathbf{X}_{:, :, i_3} = \sum_{r=1}^R b_{i_3, r} \mathbf{a}_r \mathbf{b}_r^T = \mathbf{A} \mathbf{D}_{i_3}(\mathbf{C}) \mathbf{B}^T \in \mathbb{C}^{I_1 \times I_2}, \quad (17)$$

for $i_1 = 1, \dots, I_1$, $i_2 = 1, \dots, I_2$ and $i_3 = 1, \dots, I_3$. The notation ‘:’ indicates inclusion of all subscripts along a

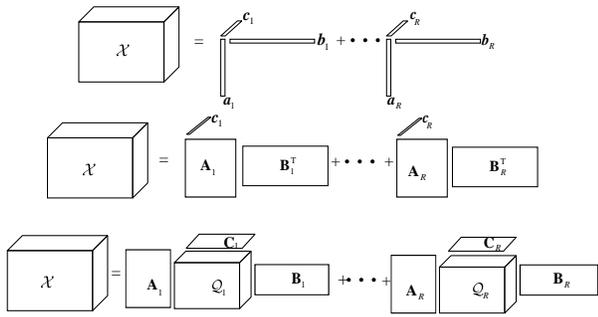

Fig. 4. Illustration of BTD models. Top: rank-(1, 1, 1) BTD or CPD; Middle: rank-(L, L, 1) BTD. Bottom: rank-(L, M, N) BTD.

particular dimension. Stacking these slices columnwise, we obtain three possible unfoldings of the tensor \mathcal{X} as

$$\mathbf{X}_{I_1 I_2 \times I_3} = \begin{bmatrix} \mathbf{B}D_1(\mathbf{A}) \\ \vdots \\ \mathbf{B}D_{I_2}(\mathbf{A}) \end{bmatrix} \mathbf{C}^T = (\mathbf{A} \diamond \mathbf{B})\mathbf{C}^T, \quad (18)$$

$$\mathbf{X}_{I_2 I_3 \times I_1} = \begin{bmatrix} \mathbf{C}D_1(\mathbf{B}) \\ \vdots \\ \mathbf{C}D_{I_3}(\mathbf{B}) \end{bmatrix} \mathbf{A}^T = (\mathbf{B} \diamond \mathbf{C})\mathbf{A}^T, \quad (19)$$

$$\mathbf{X}_{I_3 I_1 \times I_2} = \begin{bmatrix} \mathbf{A}D_1(\mathbf{C}) \\ \vdots \\ \mathbf{A}D_{I_1}(\mathbf{C}) \end{bmatrix} \mathbf{B}^T = (\mathbf{C} \diamond \mathbf{A})\mathbf{B}^T. \quad (20)$$

3) *Block term decomposition*: Block term decomposition (BTD) aims to find components with specific multilinear rank terms. The BTD framework was first introduced in [66], and the CPD and Tucker decomposition can be considered as special cases within this framework. For simplicity, we focus on third-order tensors in this subsection. The rank-1 term in CPD can be viewed as the multilinear rank-(1, 1, 1) BTD, while the Tucker decomposition can be regarded as the multilinear rank-(L, M, N) BTD with only one term; see Fig. 4 for different types of BTD. For a detailed description of additional BTD variants, the reader is referred to [67], [68].

The decomposition of 3-way tensors in rank-(L, L, 1) terms finds many applications in psychometrics, chemometrics, neuroscience, and signal processing, similar to its CPD counterpart. Rank-(L, L, 1) BTD is essentially unique under some mild conditions and its factors have explicit physical interpretations, which has been proven useful for blind source separation [69], [70] in array signal processing [71], spectrum cartography [72], and hyperspectral super-resolution (HSR) [73]. Formally, the rank-(L, L, 1) BTD of a tensor $\mathcal{X} \in \mathbb{R}^{I \times J \times K}$ is a decomposition of the form

$$\mathcal{X} = \sum_{r=1}^R \mathbf{E}_r \circ \mathbf{c}_r, \quad (21)$$

where $\mathbf{E}_r = \mathbf{A}_r \mathbf{B}_r^T \in \mathbb{R}^{I \times J}$ is a rank-L matrix, $\mathbf{A}_r \in \mathbb{R}^{I \times L}$, $\mathbf{B}_r \in \mathbb{R}^{J \times L}$, and $\mathbf{c}_r \in \mathbb{R}^K$. The factors $\{\mathbf{A}_r, \mathbf{B}_r, \mathbf{c}_r\}$ can be determined using alternating least squares (ALS), gradient-based methods, and nonlinear least squares (NLS) [67], [68].

4) *PARATUCK decomposition*: The PARATUCK decomposition combines the properties of the PARAFAC and Tucker decompositions. Taking PARATUCK2 model as an example, the element for a third-order tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$ is defined as

$$x_{i_1, i_2, i_3} = \sum_{m=1}^M \sum_{r=1}^R a_{i_1, m} b_{i_2, r} g_{m, r} c_{i_3, m}^{(\mathbf{A})} c_{i_3, r}^{(\mathbf{B})}, \quad (22)$$

where x_{i_1, i_2, i_3} is the (i_1, i_2, i_3) -th entry of \mathcal{X} , $\mathbf{A} \in \mathbb{C}^{I_1 \times M}$, $\mathbf{B} \in \mathbb{C}^{I_2 \times R}$, $\mathbf{C}^{(\mathbf{A})} \in \mathbb{C}^{I_3 \times M}$, $\mathbf{C}^{(\mathbf{B})} \in \mathbb{C}^{I_3 \times R}$. The matrices \mathbf{A} and \mathbf{B} are associated with the first and second dimensions of \mathcal{X} . $\mathbf{C}^{(\mathbf{A})}$ and $\mathbf{C}^{(\mathbf{B})}$ are interaction matrices defining the linear combination profile between the M columns of \mathbf{A} and the R columns of \mathbf{B} along the third dimension of \mathcal{X} . \mathbf{G} is the core matrix of the PARATUCK2 model. The element $g_{m, r}$ of \mathbf{G} defines the magnitude of the interaction between the m th column of \mathbf{A} and the r th column of \mathbf{B} .

PARATUCK offers more flexibility to model different communication systems that are not captured by PARAFAC models [74], [75]. The work in [76] exploits the PARATUCK2 tensor model to estimate the channel matrices for a three-hop MIMO relay system, only requiring the source to transmit the channel training sequences and relieving the relays from the burden of channel estimation.

5) *Uniqueness*: The Tucker model is not essentially unique [77]. This is because the factor matrices $\mathbf{X}^{(m)}$ and the core tensor \mathcal{Q} are not uniquely identifiable. More specifically, $\mathbf{X}^{(m)}$ and \mathcal{Q} can be replaced by $\hat{\mathbf{X}}^{(m)} = \mathbf{X}^{(m)} \Delta_m$ and $\hat{\mathcal{Q}} = \mathcal{Q} \times_{m=1}^M (\Delta_m)^{-1}$, respectively, with $\Delta_m \in \mathbb{C}^{J_m \times J_m}$ being nonsingular, without changing the tensor \mathcal{A} . That is,

$$\begin{aligned} \mathcal{A} &= \hat{\mathcal{Q}} \times_{m=1}^M \hat{\mathbf{X}}^{(m)} \\ &= \mathcal{Q} \times_{m=1}^M (\Delta_m)^{-1} \times_{m=1}^M \mathbf{X}^{(m)} \Delta_m \\ &= \mathcal{Q} \times_{m=1}^M \mathbf{X}^{(m)} \Delta_m (\Delta_m)^{-1} \\ &= \mathcal{Q} \times_{m=1}^M \mathbf{X}^{(m)} \end{aligned} \quad (23)$$

This implies that the core tensor and the factor matrices have alternatives which satisfy the decomposition model.

As opposed to the Tucker model, the PARAFAC/CPD is essentially unique, i.e., the factor matrices $\mathbf{X}^{(m)}$ in (13) are unique provided the following sufficient condition is satisfied [78]

$$\sum_{m=1}^M k_{\mathbf{X}^{(m)}} \geq 2R + (M - 1), \quad (24)$$

where $k_{\mathbf{X}^{(m)}}$ is the k -rank of the factor matrices $\mathbf{X}^{(m)} \in \mathbb{C}^{I_m \times R}$. The matrices $\mathbf{X}^{(m)}$, $m = 1, \dots, M$, are unique up to permutation and (complex) scaling of its columns [79], [80]. This means that every set of matrices $\tilde{\mathbf{X}}^{(m)}$ satisfying (15)-(17) is linked to $\mathbf{X}^{(m)}$ by

$$\tilde{\mathbf{X}}^{(m)} = \mathbf{X}^{(m)} \Pi \tilde{\Delta}_m, \quad m = 1, \dots, M, \quad (25)$$

where Π is a permutation matrix and $\{\tilde{\Delta}_m\}_{m=1}^M$ are diagonal matrices satisfying the condition

$$\prod_{m=1}^M \tilde{\Delta}_m = \mathbf{I}_R. \quad (26)$$

with $\mathbf{I}_R \in \mathbb{R}^{R \times R}$ being an identity matrix. A sufficient condition that considerably improved over the bound (24) was provided in [81], wherein an inductive method, based on the geometric notion of weak defectivity, was introduced for examining the uniqueness of tensor decompositions by means of tensors of rank one. The PARATUCK decomposition also affords uniqueness under mild conditions [74], [75]. The work in [76] examined the identifiability and uniqueness of the PARATUCK2 model, providing guidelines for parameter choices of a three-hop MIMO relay system to guarantee estimation of all channel matrices. By considering structural constraints such as Toeplitz and Vandermonde forms for some of its matrix factors in the PARATUCK2 model, Kibangou, *et al* in [82] derived additional results on the uniqueness of PARATUCK2 model in the context of a blind joint identification and equalization problem.

Similar to CPD, rank- $(L, L, 1)$ BTD also has essential uniqueness. One can arbitrarily permute the different rank- $(L, L, 1)$ terms. Within a rank- $(L, L, 1)$ term, the factors \mathbf{E}_r and \mathbf{c}_r can be arbitrarily scaled, as long as their product remains the same. The factors $\mathbf{A}_r, \mathbf{B}_r$ can be multiplied by any nonsingular matrix $\mathbf{F}_r \in \mathbb{R}^{L \times L}$ provided that $\mathbf{A}_r \mathbf{F}_r (\mathbf{B}_r \mathbf{F}_r^{-T})^T = \mathbf{A}_r \mathbf{B}_r^T$. A rank- $(L, L, 1)$ BTD is said to be essentially unique if it is subject to these trivial ambiguities. Necessary and sufficient conditions of essential uniqueness can be found in [67], [69].

Recently, coupled tensor decompositions have emerged as an important tool for handling missing data in signal processing and analysis of coupled data sets. The necessary and sufficient uniqueness conditions for coupled decompositions depend on the observed data sampling patterns. For example, the uniqueness conditions and linear algebra based algorithms of coupled CPD and coupled BTD were both considered in [83], [84], where multi-coupled subtensors were formed with partly observed data in the first two dimensions and fully observed data in the third dimension. The coupled tensor decompositions can be summarized as follows.

$$\begin{aligned} & \min_{\text{factors}} \text{Loss}(\text{subtensors}, \text{factors}) + \text{penalty}(\text{factors}) \\ & \text{subject to } \text{constraints}(\text{factors}) \end{aligned}$$

Finally, it is worth mentioning that the tensor decomposition techniques based on the data fitting principle have been extended/generalized in several ways. One important extension is the robust PARAFAC, where a trilinear alternating least squares minimization substitutes trilinear alternating least squares minimization [85]. It provides robustness to outliers (non-Gaussian error), which is a common problem in, for example, multi-user communication systems with multiple interferences, as well as jammer suppression and clutter mitigation in radar. Another recent extension is sparse tensor decomposition [86], [87] that ensures the sparsity of the decomposition and has potential applications in, for example, millimeter wave channel estimation.

III. APPLICATIONS IN WIRELESS COMMUNICATIONS

In this section, we provide an overview of tensor analysis in wireless communication. We group tensor-based methods

on the nature of the signal processing tasks undertaken and system types.

A. Blind Multiuser CDMA

We consider a typical uplink (UL) direct-sequence CDMA (DS-CDMA) communication system having one base station (BS) and M users. Let K antennas be mounted on the BS. The spreading code of user m is denoted by $\mathbf{c}_m = [c_m(1), c_m(2), \dots, c_m(L)]^T \in \mathbb{C}^{L \times 1}$, with L being the spreading gain and $c_m(l)$ representing its l th chip. The n th transmitted symbol from user m is $s_m(n)$. The fading/path loss between the BS and the user m is denoted as $\mathbf{h}_m = [h_m(1), h_m(2), \dots, h_m(K)]^T \in \mathbb{C}^{K \times 1}$. Then, the baseband output for symbol n and chip l from the k th antenna can be expressed as

$$x_{k,n,l} = \sum_{m=1}^M h_m(k) c_m(l) s_m(n). \quad (27)$$

We define $K \times N$ data matrices as

$$\mathbf{X}_{:, :, l} \triangleq \begin{bmatrix} x_{1,1,l} & x_{1,2,l} & \cdots & x_{1,N,l} \\ x_{2,1,l} & x_{2,2,l} & \cdots & x_{2,N,l} \\ \vdots & \vdots & \ddots & \vdots \\ x_{K,1,l} & x_{K,2,l} & \cdots & x_{K,N,l} \end{bmatrix} \quad (28)$$

for $l = 1, \dots, L$. With some mathematical manipulation, we can show that $\mathbf{X}_{:, :, l}$ satisfies the factorization

$$\mathbf{X}_{:, :, l} = \mathbf{H} \mathbf{D}_l (\mathbf{C})^T \quad (29)$$

where

$$\mathbf{H} \triangleq \begin{bmatrix} h_1(1) & h_2(1) & \cdots & h_M(1) \\ h_1(2) & h_2(2) & \cdots & h_M(2) \\ \vdots & \vdots & \ddots & \vdots \\ h_1(K) & h_2(K) & \cdots & h_M(K) \end{bmatrix} \quad (30a)$$

$$\mathbf{C} \triangleq \begin{bmatrix} c_1(1) & c_2(1) & \cdots & c_M(1) \\ c_1(2) & c_2(2) & \cdots & c_M(2) \\ \vdots & \vdots & \ddots & \vdots \\ c_1(L) & c_2(L) & \cdots & c_M(L) \end{bmatrix} \quad (30b)$$

$$\mathbf{S} \triangleq \begin{bmatrix} s_1(1) & s_2(1) & \cdots & s_M(1) \\ s_1(2) & s_2(2) & \cdots & s_M(2) \\ \vdots & \vdots & \ddots & \vdots \\ s_1(N) & s_2(N) & \cdots & s_M(N) \end{bmatrix}. \quad (30c)$$

With the factorization in PARAFAC model, the spreading codes $\mathbf{C} \in \mathbb{C}^{L \times M}$, information symbols $\mathbf{S} \in \mathbb{C}^{N \times M}$, and the path fading loss $\mathbf{H} \in \mathbb{C}^{K \times M}$ can be recovered as long as the decomposition uniqueness condition is satisfied. We note that the model in (29) does not consider practical constraints, such as frequency-selective channel, time synchronization issues, MIMO case, etc.

The work [80] was the first to introduce tensor model for signal processing in wireless communication systems. The authors proposed a blind PARAFAC model-based separation-equalization-detection receiver for DS-CDMA multiuser systems for the case of no ISI. The blind receiver was shown to achieve the same performance as that of the non-blind

minimum mean-squared error (MMSE) receiver. Owing to the fact that it did not require statistical independence or knowledge of the codes, the receiver offered a higher flexibility for incorporation into different types of systems compared to earlier approaches.

The work in [25] proposed a two-stage blind tensor based detector for the UL communication of a wideband-CDMA system subject to large delay spread, when ISI is present. The low-rank decomposition of the 3-D received data enabled an Finite Impulse Response (FIR) MIMO-CDMA problem to be converted into multiple standard independent FIR Single-Input Multiple-Output (SIMO) problems; the latter were solved using known techniques, such as the Hankel kernel approach. The paper [26], on the other hand, devised a constrained tensor modeling approach for a UL CDMA communication system where the BS and the users employed multiple antennas. Two constraint matrices were considered to respectively control the spatial spreading of the data streams and the spatial reuse of the spreading codes. A systematic design procedure for the canonical allocation matrices was developed which derived a finite set of multiple-antenna schemes for a fixed number of transmit antennas. Identifiability of the proposed tensor model was also determined to guarantee blind symbol recovery. The work [88] generalized the model of [26] to the MIMO case by incorporating data stream, spreading code, and antenna allocations through a new tensor decomposition called constrained factor (CONFAC) decomposition.

The paper [70] employed BTDs to address the case of DS-CDMA with ISI. Assuming ISI to have an impact over at most R symbols, the l th chip of the n th symbol of the m th user signal can be expressed as

$$z_{ln}^m = \sum_{r=0}^R \mathbf{E}_m(l, r) s_m(n-r), \quad (31)$$

where $\mathbf{E}_m(l, r)$ denotes the overall impulse response of the l th chip and the most recent r th symbol. In this case, the baseband output for symbol n and chip l from the k th antenna is $x_{k,n,l} = \sum_{m=1}^M h_m(k) z_{ln}^m$, which can be expressed in tensor form as

$$\mathcal{X} = \sum_{m=1}^M \mathbf{h}_m \circ (\mathbf{E}_m \mathbf{S}_m), \quad (32)$$

where $\mathbf{E}_m \in \mathbb{R}^{L \times R}$ and $\mathbf{S}_m \in \mathbb{R}^{R \times N}$ is a Toeplitz matrix with $s_m(n-r)$ as its (r, n) th element. Eq. (32) admits BTD in rank- $(1, R, R)$ terms. Details of the corresponding essential uniqueness condition and blind deconvolution algorithm can be found in [70], [89].

The authors in [24] unified the received signal model of three multiuser systems, namely, a temporally oversampled system, a DS-CDMA system, and an OFDM system, into a tensor (3-D) PARAFAC model. Each considered multiuser system employed multiple antennas at the receiver and was assumed to be subject to frequency-selective multipath fading. A new tensor-based receiver was designed that performed, in an iterative fashion, multiuser signal separation by determining the PARAFAC model parameters and signal equalization via

subspace methods. Simulation results showed that the tensor-based receiver provided performance close to the MMSE solution with a perfect knowledge of the propagation parameters.

B. Space-Time Frequency (STF) MIMO Systems

In wireless communication systems, incorporation of oversampling, spreading, multiplexing, diversity, and other operations yields multi-dimensional received signals, for which the tensor models are a natural fit. We consider a typical multi-carrier MIMO wireless communication system, where the BS uses M transmit antennas, R data streams, and F subcarriers. A total of K receive antennas are employed. We assume the transmission to be decomposed into P data blocks, with each block consisting of N symbol periods. The transmitted symbols are spread and multiplexed in space (multiple antennas), time (time blocks and time spreading), and frequency (multi-carriers) domains. We denote by $s_{n,r}$ the n th symbol of the r th data stream, and $\mathbf{W} \in \mathbb{C}^{M \times R}$ is the coding matrix that maps the signals from the data streams to the antennas.

For a fixed symbol period p and subcarrier f , the (m, p, f) th STF coded signal associated with the m th transmit antenna, p th block, and f th subcarrier is generated by two allocation tensors, namely, the stream allocation tensor $\mathcal{C}^{(S)} \in \mathbb{R}^{F \times P \times R}$ and the antenna allocation tensor $\mathcal{C}^{(H)} \in \mathbb{R}^{F \times P \times M}$. The former determines the time-frequency mapping of the R data streams across P blocks and F subcarriers, while the latter dictates the time-frequency mapping of the M transmit antennas. The elements of both tensors assume a value equal to zero or unity.

The coded signal can be formed into a fourth-order tensor $\mathcal{U} \in \mathbb{C}^{F \times M \times N \times P}$, where the (f, m, n, p) th element corresponds to the f th subcarrier, m th transmit antenna, n th symbol period, and p th data block, and is given by

$$\begin{aligned} u_{f,m,n,p} &= \sum_{r=1}^R w_{m,r} s_{n,r} c_{f,p,m}^{(H)} c_{f,p,r}^{(S)} \\ &= \sum_{r=1}^R t_{f,m,r,p} s_{n,r}, \end{aligned} \quad (33)$$

with

$$t_{f,m,r,p} \triangleq w_{m,r} c_{f,p,m}^{(H)} c_{f,p,r}^{(S)}. \quad (34)$$

We define $\mathcal{H} \in \mathbb{C}^{F \times K \times M}$ as the channel tensor for the MIMO-OFDM communication system. The fading coefficients are assumed to be constant during P blocks. For the noiseless case, the received signal tensor $\mathcal{X} \in \mathbb{C}^{F \times K \times N \times P}$, corresponding to the f th subcarrier and received at the k th antenna during the n th symbol period of the p th data block, is given by

$$\begin{aligned} x_{f,k,n,p} &= \sum_{m=1}^M h_{f,k,m} u_{f,m,n,p} \\ &= \sum_{m=1}^M \sum_{r=1}^R t_{f,m,r,p} h_{f,k,m} s_{n,r}. \end{aligned} \quad (35)$$

The received signal tensor follows a generalized constrained PARATUCK2 model. Using the mode- n product definition

from (8), we can write the f th tensorial slice of $\mathcal{X} \in \mathbb{C}^{F \times K \times N \times P}$, containing all received signals associated with the subcarrier f , as

$$\mathcal{X}^{(f)} = \mathcal{T}^{(f)} \times_1 \mathbf{H}^{(f)} \times_2 \mathbf{S}, \quad (36)$$

where $\mathcal{X}^{(f)} \triangleq \mathcal{X}_{f, :, :, :} \in \mathbb{C}^{K \times N \times P}$, $\mathcal{T}^{(f)} \triangleq \mathcal{T}_{f, :, :, :} \in \mathbb{C}^{M \times R \times P}$, $\mathbf{H}^{(f)} \triangleq \mathbf{H}_{f, :, :} \in \mathbb{C}^{K \times M}$ and $\mathbf{S} \in \mathbb{C}^{N \times R}$. Fig. 5 depicts the block-diagram of the STF coding structure.

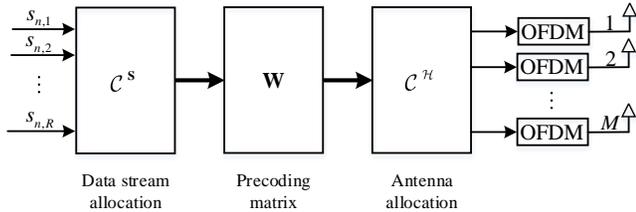

Fig. 5. SFT coding structure.

By introducing extra diversity into the transmitting signal, e.g., space, time, frequency and code, the tensor modeling is able to encode the signal and exploit the coding features. Following [80], the flexible class of Khatri-Rao Space-Time (KRST) codes based on the PARAFAC tensor model was also developed in [32]. The work in [90] combined space-frequency spreading and multiplexing functionalities for MIMO multi-stream multi-carrier systems, while allowing a semi-blind joint channel estimation and detection using the PARAFAC model.

A new tensorial approach based on a tensor space-time (TST) coding was proposed in [33] for MIMO wireless communication systems. The received signals assumed the form of a fourth-order tensor which was shown to satisfy a PARATUCK- (N_1, N) model with $N_1 = 2$ and $N = 4$. The uniqueness conditions for the PARATUCK- (N_1, N) model were also established therein. Semi-blind receivers based on ALS, Levenberg-Marquardt (LM) and the Kronecker Least Squares methods were designed for both the TST and STF systems.

In [34], a transmission scheme based on two allocation matrices for selection of antennas and data streams was modeled utilizing only the space and time domains. A generalized fourth-order PARATUCK2 tensor model for MIMO communications with STF spreading-multiplexing was proposed in [35]. The core of this fourth-order tensor was essentially composed of two third-order interaction tensors. Data streams (multiplexing degree) and transmit antennas (space) were allocated to time blocks (time) and subcarriers (frequency). A blind receiver based on LM algorithm was proposed for the generalized fourth-order PARATUCK2 model.

The authors in [36] proposed two new classes of constrained tensor models, called the generalized PARATUCK- (N_1, N) model and the generalized Tucker- (N_1, N) model, with high-order tensors being the factors of the decompositions. A new tensor STF coding which led to a generalized PARATUCK- $(2,5)$ model was proposed for MIMO OFDM-CDMA systems. Two semi-blind receivers, one iterative and the other in closed-form, were proposed for a joint channel and symbol estimation. The former was based on a two-step ALS algorithm,

while the latter comprised a low-complexity solution based on Kronecker product least squares estimation.

In [37], a two-step tensor-based receiver based on the fourth-order PARATUCK2 model was proposed for a modified space-time (ST) coding scheme which incorporated a formatting filter. In the first step, closed-form channel estimation was performed by means of Kronecker and Khatri-Rao factorizations. In the second step, the transmitted symbols were linearly decoded by exploiting the estimated channel. Simulation results demonstrated the effectiveness of the tensor-based receiver in terms of normalized mean squared error and bit error rate (BER).

C. Cooperative/Relay Systems

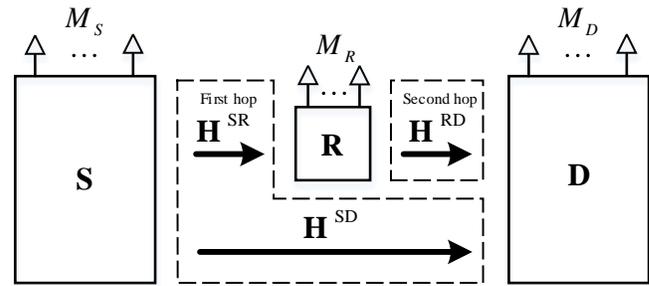

Fig. 6. Two-hop relay communication system.

We consider a typical amplify-and-forward (AF) two-hop cooperative system with a source node (S), a destination node (D), and a relay (R), as shown in Fig. 6. The respective numbers of antennas at the source, destination, and the relay are assumed to be M_S , M_D , and M_R . Matrices $\mathbf{H}^{SD} \in \mathbb{C}^{M_D \times M_S}$, $\mathbf{H}^{SR} \in \mathbb{C}^{M_R \times M_S}$ and $\mathbf{H}^{RD} \in \mathbb{C}^{M_D \times M_R}$ denote the channel of the direct link to destination (SD link), the channel between the source and the relay (SR link), and the channel between the relay and the destination (RD link), respectively. Let $\mathbf{S} \in \mathbb{C}^{N \times M_S}$ be the information symbol matrix during N time-blocks. A code matrix $\mathbf{C} \in \mathbb{C}^{P \times M_S}$ is used, where P is the number of symbol periods in a time block. The transmitted signal at the n th time block is given by

$$\mathbf{X}_n = D_n(\mathbf{S})\mathbf{C}^T \in \mathbb{C}^{M_S \times P}. \quad (37)$$

1) *Model of the SD Link:* The n th received signal is given by

$$\mathbf{Y}_{:, :, n}^{(SD)} = \mathbf{H}^{(SD)}\mathbf{X}_n = \mathbf{H}^{(SD)}D_n(\mathbf{S})\mathbf{C}^T \in \mathbb{C}^{M_D \times P}. \quad (38)$$

where $\mathbf{Y}_{:, :, n}$ is the n th slice of the third-order received signal tensor $\mathcal{Y}^{(SD)} \in \mathbb{C}^{M_D \times P \times N}$. Eq. (38) represents a PARAFAC decomposition of $\mathcal{Y}^{(SD)}$. The elements of $\mathcal{Y}^{(SD)}$ can be expressed as

$$y_{m_D, p, n}^{(SD)} = \sum_{m_S=1}^{M_S} h_{m_D, m_S}^{SD} c_{p, m_S} s_{n, m_S}. \quad (39)$$

Three unfolded forms of this PARAFAC model are given by

$$\mathbf{Y}_{PN \times M_D}^{(SD)} = (\mathbf{S} \diamond \mathbf{C}) \left(\mathbf{H}^{(SD)} \right)^T, \quad (40)$$

$$\mathbf{Y}_{NM_D \times P}^{(SD)} = \left(\mathbf{H}^{(SD)} \diamond \mathbf{S} \right) (\mathbf{C})^T, \quad (41)$$

$$\mathbf{Y}_{M_D P \times N}^{(SD)} = (\mathbf{C} \diamond \mathbf{H}^{(SD)}) (\mathbf{S})^T. \quad (42)$$

2) *Model of the Source-Relay-Destination (SRD) Link:* The signals received at the relay are first stored and then an AF matrix $\mathbf{G} \in \mathbb{C}^{N \times M_R}$ is used to code the stored signals, which are transmitted through the channel $\mathbf{H}^{(RD)}$. The received signals at the destination via the relay form a third-order tensor $\mathcal{Y}^{(SRD)} \in \mathbb{C}^{M_D \times P \times N}$ whose n th slice is given by

$$\mathbf{Y}_{:, :, n}^{(SRD)} = \mathbf{H}^{(RD)} D_n(\mathbf{G}) \mathbf{H}^{(SR)} D_n(\mathbf{S}) \mathbf{C}^T \in \mathbb{C}^{M_D \times P}. \quad (43)$$

Eq. (43) represents a PARATUCK2 decomposition of the tensor $\mathcal{Y}^{(SRD)}$, whose elements can be written as

$$y_{m_D, p, n}^{(SRD)} = \sum_{m_R=1}^{M_R} \sum_{m_S=1}^{M_S} h_{m_D, m_R}^{(RD)} g_{n, m_R} h_{m_R, m_S}^{(SR)} c_{p, m_S} s_{n, m_S}. \quad (44)$$

In the PARAFAC and PARATUCK2 decompositions, the uniqueness can be established under specific conditions. Both semi-blind and blind receivers have been investigated to estimate the channels, $\mathbf{H}^{(SR)}$ and $\mathbf{H}^{(DR)}$, and the symbol \mathbf{S} by means of algorithms, such as the ALS. In cooperative systems, the system reliability strongly depends on the accuracy of channel state information (CSI) of all links between the source, relays and destination. Under the assumption that CSI is not available, the authors in [41] proposed a blind receiver model for UL multiuser cooperative diversity systems by exploiting a unified formulation of the received signals as a PARAFAC model. Three relay protocols were considered, namely, AF, fixed decode-and-forward, and selective decode-and-forward. In [42], a simplified KRST coding was adopted at the transmission source in a two-hop AF cooperative scheme. Three different receivers using the PARAFAC and PARATUCK2 models for the SD and SRD links were designed. Simulation results demonstrated the superior performance of these receivers over supervised approaches in terms of the BER.

In [43], the author proposed the nested Tucker decomposition (NTD) model. Then, by exploiting a tensor space-time coding structure at both the source and the relay nodes in a one-way two-hop MIMO relay communication system, an NTD of the fourth-order tensor was formed at the destination. Two semi-blind receivers and two supervised receivers were derived to jointly estimate the transmitted information symbols and the two individual relay channels. The authors in [44] performed joint channel estimation for a three-hop MIMO system with an AF relaying protocol. ALS algorithm was used by coupling PARAFAC and Tucker3 tensor models for the received signals to iteratively estimate the channel matrices. Simulation results corroborated the effectiveness of the joint channel estimator when compared to two sequential estimators. In [91], a one-way multi-hop AF relaying system was modeled based on a generalized nested PARAFAC decomposition. Under the assumption of KRST coding implemented at each relay, a sequential closed-form semi-blind receiver was designed, wherein the information symbols and the individual channels were jointly estimated. For OFDM-based cooperative communication systems, a tensor-based blind signal recovery scheme was devised in [92]. The received multi-carrier signals were modeled as a 3-D tensor and a PARAFAC decomposition-based blind receiver algorithm was employed for data detection. The work in [93] proposed two ST coding

schemes, MKRST and MKronST, for multiple-antenna one-way two-hop MIMO relay system. These coding schemes generalized the standard Khatri-Rao coding by introducing extra space/time diversities. Parallel non-iterative decoding methods were proposed for estimating the symbol matrix. In [94], the authors considered the multi-relaying systems. Two tensor-based receivers were proposed to jointly estimate the channels and symbols in a semi-blind fashion. By exploiting the structure of the received signals, the authors showed that the data for the relay-assisted link after ST decoding has a Kronecker structure, which can be recast as a rank-one tensor based on PARAFAC analysis. The simulation results demonstrated that the proposed receiver design has good performance-complexity trade-off.

D. Time-varying Channel Modeling

Tensor decompositions were considered for on-line applications in [95], where the data were assumed to be serially acquired and/or the underlying model was considered to change frequently, resulting in a time-varying wireless communication system. Given the PARAFAC decomposition of a tensor at instant t , two adaptive low-complexity algorithms were provided to obtain the decomposition at instant $t + 1$ by appending a new slice in the time dimension, and their excellent tracking capability was validated through simulation.

Doppler shifts in a time-varying mmWave scenario were considered in [96]. The channel was assumed to have block-sparse and low-rank characteristics, since the change in angle was much slower than that in path gain. By exploiting these characteristics, a two-stage method was proposed. In the first stage, Block Orthogonal matching pursuit algorithm was used to estimate the angles-of-arrival (AoAs)/angles-of-departure (AoDs). Based on the angle estimates, PARAFAC decomposition was used to estimate the Doppler shifts and path gains in the second stage. Furthermore, the proposed algorithm was shown to be close to the Cramer-Rao Lower Bound (CRLB). For downlink (DL) multiuser-MIMO communications over a time-varying channel, a transmission frame structure was proposed in [97], wherein the angle and the channel gain were to be estimated. By leveraging the sparse nature of mmWave channels, an adaptive angle estimation algorithm was devised. The angle estimates were used to design pilot beamforming for estimating the path gains. For the same assumption of slower variations in angle than path gains, the authors in [98] proposed a two-stage tensor decomposition based method for a single receiver. Doppler shift estimation was achieved based on the estimated angles.

E. mmWave Communication System

Millimeter wave channels have a sparse scattering nature, leading to their low-rank structures and spread in the form of clusters of paths over the angular domains, including the AoA, AoD, and elevation. This joint sparse and low-rank structure renders the application of tensor models suitable in mmWave communication systems.

Consider a point-to-point UL mmWave MIMO system, which comprises M antennas at the BS and N antennas

at the MS. Beamforming techniques are implemented to address the severe path losses at millimeter wavelengths. Analog beamforming is used in both BS and MS with one radio-frequency chain. At time instant t , the symbol $s(t)$ is transmitted through an analog beamforming vector $\bar{\mathbf{f}}(t) \in \mathbb{C}^N$. The receiver combines the signals with receive beamforming vector $\mathbf{w}(t) \in \mathbb{C}^M$. The combined signal at the receiver can be expressed as

$$y(t) = \mathbf{w}^H(t)\mathbf{H}\bar{\mathbf{f}}(t)s(t) + \mathbf{w}^H(t)\mathbf{n}(t) \quad \forall t = 1, \dots, T, \quad (45)$$

where $\mathbf{H} \in \mathbb{C}^{M \times N}$ is the channel matrix and $\mathbf{n}(t) \in \mathbb{C}^M$ denotes additive Gaussian noise. For mmWave operation, the channel is usually characterized by a geometric model [96]

$$\mathbf{H} = \sum_{l=1}^L \alpha_l \mathbf{a}_{BS}(\theta_l) \mathbf{a}_{MS}^H(\psi_l), \quad (46)$$

where L is the number of paths, α_l is the complex gain associated with the l th path, and θ_l and ψ_l are the AoA and AoD, respectively. The vectors \mathbf{a}_{BS} and \mathbf{a}_{MS} represent the array response vectors and are given by

$$\mathbf{a}_{BS}(\theta_l) = \frac{1}{\sqrt{M}} \left[1, e^{j\frac{2\pi}{\lambda}d \sin(\theta_l)}, \dots, e^{j(M-1)\frac{2\pi}{\lambda}d \sin(\theta_l)} \right]^T, \quad (47)$$

$$\mathbf{a}_{MS}(\psi_l) = \frac{1}{\sqrt{N}} \left[1, e^{j\frac{2\pi}{\lambda}d \sin(\psi_l)}, \dots, e^{j(N-1)\frac{2\pi}{\lambda}d \sin(\psi_l)} \right]^T. \quad (48)$$

The channel matrix can be further formulated as

$$\mathbf{H} = \mathbf{A}_{BS} \mathbf{H}_v \mathbf{A}_{MS}^H \quad (49)$$

where $\mathbf{A}_{BS} \triangleq [\mathbf{a}_{BS}(\phi_1), \dots, \mathbf{a}_{BS}(\phi_{N_1})] \in \mathbb{C}^{M \times N_1}$ is the overcomplete dictionary matrix consisting of the BS steering vectors corresponding to N_1 discretized arrival angles. Likewise, $\mathbf{A}_{MS} \in \mathbb{C}^{N \times N_2}$ can be obtained using MS steering vectors corresponding to N_2 discretized departure angles. The matrix $\mathbf{H}_v \in \mathbb{C}^{N_1 \times N_2}$ is sparse, with L non-zero entries corresponding to the channel path gains, $\{\alpha_l\}$. By exploiting the Kronecker product properties of (2) and (3), the received signal can be rewritten as

$$\begin{aligned} y(t) &= \mathbf{w}^H(t) \mathbf{A}_{BS} \mathbf{H}_v \mathbf{A}_{MS}^H \bar{\mathbf{f}}(t) s(t) + n'(t) \\ &= \left[(\mathbf{A}_{MS}^H \bar{\mathbf{f}}(t))^T \otimes (\mathbf{w}^H(t) \mathbf{A}_{BS}) \right] \mathbf{h} + n'(t) \\ &= (\bar{\mathbf{f}}^T(t) \otimes \mathbf{w}^H(t)) (\mathbf{A}_{MS}^* \otimes \mathbf{A}_{BS}) \mathbf{h} + n'(t) \end{aligned} \quad (50)$$

where $\mathbf{f}(t) = \bar{\mathbf{f}}(t)s(t)$, $\mathbf{h} \triangleq \text{vec}(\mathbf{H}_v)$ and $n'(t)$ is the equivalent noise. Collecting the received signals as $\mathbf{y} \triangleq [y(1), \dots, y(T)]^T$, we have

$$\begin{aligned} \mathbf{y} &= \begin{bmatrix} \bar{\mathbf{f}}^T(1) \otimes \mathbf{w}^H(1) \\ \vdots \\ \bar{\mathbf{f}}^T(T) \otimes \mathbf{w}^H(T) \end{bmatrix} (\mathbf{A}_{MS}^* \otimes \mathbf{A}_{BS}) \mathbf{h} + \mathbf{n}' \\ &\triangleq \boldsymbol{\Psi} \mathbf{h} + \mathbf{n}'. \end{aligned} \quad (51)$$

The above model together with the unique characteristics of mmWave time-varying channels can be exploited to estimate AoAs/AoDs. For example, the work in [99] considered the channel estimation problem for multi-user UL MIMO

mmWave communication systems, where both the BS and the users were assumed to have hybrid beamforming structures. The low-rank structure of the received data was exploited within a PARAFAC model and a layered pilot transmission scheme was devised to reduce the training overhead. The conditions to ensure the uniqueness of the decomposition were used for the beamformer design. Similar to [99], the author in [100] considered the problem of DL channel estimation for mmWave MIMO-OFDM systems. The authors proposed a PARAFAC decomposition-based method for channel parameter estimation, including angles, time delays, and fading coefficients. The analysis revealed that the uniqueness of the CPD could be guaranteed with a small training overhead. The CRLB was also developed as a benchmark for the proposed tensor based algorithm.

The work in [101] combined dual-polarized (DP) antenna arrays with the double directional (DD) channel model for DL channel estimation. The combination was modeled as a low-rank four-way tensor and tensor decomposition algorithms were used to effectively estimate the associated channel parameters. Furthermore, the DD channel with DP arrays was shown to be identifiable under very mild conditions. In [102], a compressed tensor decomposition algorithm was added to alleviate the training overhead. In [103], the practical hardware impairment, i.e., carrier frequency offset (CFO), was considered. The authors proposed a joint CFO and channel estimation method based on tensor modeling and compressed sensing which was shown via simulation to be more robust to a small number of channel measurements. The work in [104] discussed the channel estimation problem under a MIMO-OFDM transmission assumption. A tensor compressive sensing (tensor-CS) model was formulated by assuming that the channel is compressively sampled in space (radio-frequency chains), time (symbol periods), and frequency (pilot subcarriers). That is,

$$\mathcal{Y} = \mathcal{H} \times_1 (\mathbf{Q} \mathbf{A}_R) \times_2 (\mathbf{X} \mathbf{A}_T) \times_3 (\mathbf{F} \mathbf{A}_F) + \mathcal{Z}. \quad (52)$$

where $\mathbf{X} \in \mathbb{C}^{T_p \times N}$, $\mathbf{Q} \in \mathbb{C}^{L_r \times M}$, $\mathbf{F} \in \mathbb{C}^{F_p \times F}$ denote the respective pilot sequence, combining, and subcarrier selection matrices, T_p and F_p denote the respective numbers of OFDM symbols and subcarriers, F is the number of frequency bins, L_r is the number of radio-frequency chains at the receiver, $\{\mathbf{A}_R, \mathbf{A}_T, \mathbf{A}_F\}$ represents the codebook set of arrival angles, transmit angles, and delays, and \mathcal{Z} is the noise tensor. The tensor \mathcal{H} represents the virtual MIMO channel and can be seen as a generalization of (49) by adding two additional dimensions, namely, time/Doppler and delay/frequency. Clearly, the tensor-CS model of (52) coincides with a sparse Tucker3 model, where the associated core tensor is \mathcal{H} . This tensor-CS model was then used as the basis for the formulation of a tensor-orthogonal matching-pursuit estimator. The authors in [105] addressed the problem of joint DL and UL channel estimation for mmWave MIMO systems using a tensor modeling approach. Assuming a closed-loop and multifrequency-based channel training framework, the algorithms developed therein jointly estimated the DL and UL channels by concentrating most of the processing burden for channel estimation at the BS.

IV. APPLICATIONS IN MIMO RADAR

The higher dimensional signal structures inherent in MIMO radar invite tensor-based signal processing solutions to the target parameter estimation and transmit beamforming problems. The use of tensor models and multilinear algebraic methods in MIMO radar is not yet at the same level of maturity as in wireless communications. Nonetheless, there exist some interesting results. Below, we provide an overview of tensor-based methods in bistatic and monostatic MIMO radar systems.

A. Tensor Techniques for Target Parameter Estimation in MIMO Radar

For a bistatic MIMO radar with an M -element transmit array and an N -element receive array, the received signal model under the assumption of orthogonal transmit waveforms and a coherent processing interval (CPI) containing Q pulses can be expressed as [57], [58]

$$\mathbf{Y} = (\mathbf{A} \diamond \mathbf{B})\mathbf{C}^T + \mathbf{Z}, \quad (53)$$

where $\mathbf{Y} \in \mathbb{C}^{MN \times Q}$ contains the received data after matched filtering, \mathbf{Z} is the spatially and temporally white additive noise, $\mathbf{C}^T \in \mathbb{C}^{P \times Q}$ contains the reflection coefficients of P targets corresponding to Q pulses, and $\mathbf{A} \in \mathbb{C}^{M \times P}$ and $\mathbf{B} \in \mathbb{C}^{N \times P}$ denote the respective steering matrices for transmit and receive arrays. Arranging the matched-filter outputs as a tensor $\mathcal{Y} \in \mathbb{C}^{M \times N \times Q}$ and following the definitions of the matrix unfoldings in Section II-B2, it can be observed that model (53) represents the PARAFAC decomposition. As such, target parameter estimation can proceed within the PARAFAC framework.

The target AoAs and AoDs were estimated using the PARAFAC model in [57] under narrowband far-field assumptions. The p th column of matrix \mathbf{A} (matrix \mathbf{B}) in (53) captures the delays across the different transmit (receive) antennas relative to a reference transmit (receive) antenna for a plane wavefront departing in (arriving from) the direction of the p th target. Two different models for target radar cross-section (RCS) fluctuations were considered. Swerling I model assumes the RCS coefficients to be constant over the CPI, whereas in the Swerling II model, the RCS coefficients vary independently from pulse to pulse. Conditions for essential uniqueness guarantees were established which yielded useful bounds on the number of resolvable targets.

The works in [106], [107] tackled the problem of target estimation in bistatic MIMO radar under narrowband assumption via low-rank tensor completion. The proposed solution in [106] employed an accelerated proximal gradient line-search algorithm coupled with rank detection to obtain an accurate rank estimate in a noisy environment with an unknown number of targets. In [107], the cross-covariance matrix of the matched-filtered outputs was modeled as a Nested-PARAFAC decomposition of a fourth-order covariance tensor. The structure of this decomposition was exploited in a two-stage algorithm for joint AoA and AoD estimation of multiple targets based on double alternating least squares.

The works in [58], [59], on the other hand, proposed tensor-based near-field localization algorithms for targets located closer to the transmit and/or receive arrays of a bistatic MIMO radar. In this case, the p th column of matrix \mathbf{A} (matrix \mathbf{B}) was defined in terms of the exact path differences under spherical wavefronts between the reference transmit (receive) antenna and other antennas in the transmit (receive) array for the p th target. The estimated target parameters included the AoAs, the AoDs, and the target distances from transmit and receive reference antennas. In [59], the parameters were obtained through iteratively optimizing a least-squares cost function defined with respect to the elements of \mathbf{A} and \mathbf{B} . Alternatively, the authors in [58] first estimated \mathbf{A} and \mathbf{B} as factor matrices in an approximate low rank CPD of the tensor \mathcal{Y} , which were then used to estimate the target parameters by solving systems of linear equations.

We note that the model in (53) as well as the aforementioned methods do not take into account the effects of array mutual coupling (MC) on target parameter estimation. MC however occurs in practice and can lead to performance degradation if not properly compensated. Both higher-order singular value decomposition (HOSVD) and PARAFAC decomposition-based methods have been recently proposed for accurate target localization using MIMO radar in the presence of mutual coupling [60], [108], [109].

A tensor-based sub-Nyquist monostatic MIMO radar was proposed in [110] which used undersampled measurements in spectral, spatial, Doppler, and temporal domains to jointly estimate target AoAs, range, and Doppler. The received signals were modeled as a partial third-order tensor. On-grid target parameters were estimated by solving a sparse recovery problem using tensor orthogonal matching pursuit, whereas a nuclear-norm regularized tensor completion method was employed for off-grid target parameters. The lower bounds on the total numbers of antenna channels, transceiver frequencies, and pulses required for perfect recovery of both on-grid and off-grid targets were also determined.

B. Tensor Techniques for Transmit Array Interpolation and Beamspace Design in MIMO Radar

Together with waveform design, TB design [61], [111]–[113] is one of the fundamental problems in MIMO radar with colocated antennas. While designing TB, certain properties such as rotational invariance property (RIP) at the receive array can be ensured via TB matrix at the transmit array for a monostatic MIMO radar [61]. It is especially useful for reducing significantly the complexity of solving the target localization problem (e.g., AoA estimation – azimuth and elevation for two-dimensional (2-D) arrays) at the receive array. If the RIP is ensured between more than two virtual subarrays (the solution for two subarrays related to each other through RIP is the classical ESPRIT), the received signals in MIMO radar can be arranged in a tensor and tensor algebra then becomes the main tool for designing localization algorithms.

For example, consider a 2-D monostatic MIMO radar, with its transmit and receive arrays placed on a plane and

having arbitrary geometries. The receive array consists of antenna elements randomly selected from the transmit array. Let the transmit antenna elements be located at the position $\mathbf{p}_m \triangleq [x_m, y_m]^T$, $m = 1, 2, \dots, M$. Then the $M \times 1$ steering vector of the transmit array can be expressed as

$$\mathbf{a}(\theta, \phi) \triangleq [e^{-j2\pi\mathbf{u}^T(\theta, \phi)\mathbf{p}_1}, \dots, e^{-j2\pi\mathbf{u}^T(\theta, \phi)\mathbf{p}_M}]^T \quad (54)$$

where $\mathbf{u}(\theta, \phi) \triangleq [\sin\theta \cos\phi, \sin\theta \sin\phi]^T$ represents the propagation vector, and θ, ϕ are the elevation and azimuth angles, respectively. Similarly, the steering vector of the N -element receive array can be expressed as

$$\mathbf{b}(\theta, \phi) \triangleq [e^{-j2\pi\mathbf{u}^T(\theta, \phi)\mathbf{p}_1}, \dots, e^{-j2\pi\mathbf{u}^T(\theta, \phi)\mathbf{p}_N}]^T. \quad (55)$$

Let $s_m(t)$ be the complex envelope of the m th transmit signal where t represents the fast time, and then $\{s_m(t)\}_{m=1}^M$ be a set of M waveforms. Each waveform $s_m(t)$ has unit energy, and all waveforms are orthogonal to each other during one pulse, i.e., $\int_T s_m(t)s_{m'}^*(t)dt = \delta(m - m')$, where T is the radar pulse duration, $\delta(\cdot)$ denotes the Dirac delta function, and L is the number of samples per pulse period. Therefore, the signal radiated towards a spatial region of interest is

$$\zeta(t, \theta, \phi) = \mathbf{a}^T(\theta, \phi)\mathbf{s}(t) = \sum_{m=1}^M a_m(\theta, \phi)s_m(t) \quad (56)$$

where $\mathbf{s}(t) \triangleq [s_1(t), \dots, s_M(t)]^T$ and $a_m(\theta, \phi)$ is the m th element of $\mathbf{a}(\theta, \phi)$.

Assuming that the RCS coefficients obey Swerling II model, for the case of K targets located in a spatial sector of interest, the received MIMO observation vector can be expressed as

$$\mathbf{x}(t, q) = \sum_{k=1}^K \beta_k(q)(\mathbf{a}^T(\theta_k, \phi_k)\mathbf{s}(t))\mathbf{b}(\theta_k, \phi_k) + \mathbf{n}(t, q) \quad (57)$$

where q represents the slow time index, $\beta_k(q)$ is the RCS coefficient of k th target with variance σ_β^2 , and $\mathbf{n}(t, q)$ is the noise vector modeled as complex spatial and temporal white Gaussian process. Using the orthogonality property of transmit waveforms, the received data vector corresponding to the m th waveform after matched-filtering can be obtained as

$$\mathbf{y}_m(q) = \sum_{k=1}^K (a_m(\theta_k, \phi_k)\mathbf{b}(\theta_k, \phi_k))\beta_k(q) + \mathbf{z}(q) \quad (58)$$

where $\mathbf{y}_m(q) \in \mathbb{C}^{N \times 1}$ and $\mathbf{z}(q)$ is the noise vector after matched-filtering whose covariance matrix is given by $\sigma_n^2 \mathbf{I}_N$. Hence, we stack $\mathbf{y}_m(q)$, $m = 1, \dots, M$, to form the receive vector,

$$\mathbf{y}(q) = (\mathbf{A}(\theta, \phi) \diamond \mathbf{B}(\theta, \phi))\boldsymbol{\beta}(q) + \mathbf{z}(q) \quad (59)$$

where $\boldsymbol{\beta}(q) \triangleq [\beta_1(q), \dots, \beta_K(q)]^T$ is the vector of RCS coefficients during the q th pulse, $\mathbf{A}(\theta, \phi) \triangleq [\mathbf{a}(\theta_1, \phi_1), \dots, \mathbf{a}(\theta_K, \phi_K)]$ is the $M \times K$ transmit steering matrix, and $\mathbf{B}(\theta, \phi) \triangleq [\mathbf{b}(\theta_1, \phi_1), \dots, \mathbf{b}(\theta_K, \phi_K)]$ is the $N \times K$ receive steering matrix.

Using the TB matrix at the transmitter, the received signal in q th pulse is given as

$$\tilde{\mathbf{y}}(q) = \mathbf{B}(\theta, \phi)\boldsymbol{\Sigma}(q)\mathbf{A}^H(\theta, \phi)\mathbf{W}\mathbf{s}(t) + \mathbf{z}(q) \quad (60)$$

where $\boldsymbol{\Sigma}(q) = \text{diag}(\boldsymbol{\beta}(q))$ and \mathbf{W} is the TB matrix. Considering Q pulses, the received TB MIMO radar signal matrix $\tilde{\mathbf{Y}} \in \mathbb{C}^{MN \times Q}$ can be formed. Here, \tilde{M} is the dimension of the transmit signal after TB transform. Then, the corresponding TB MIMO radar tensor model can be expressed as

$$\mathcal{Y} = \mathcal{A} \times_R \mathbf{P} + \mathcal{Z} \quad (61)$$

where steering tensor \mathcal{A} is formed by stacking K targets' steering tensor \mathcal{A}_k together, $\mathbf{P} \triangleq [\boldsymbol{\beta}(1), \boldsymbol{\beta}(2), \dots, \boldsymbol{\beta}(Q)]$ contains K vectors of targets' RCS coefficients for Q pulses, and \mathcal{Z} denotes the zero-mean Gaussian noise samples, and R represents the R th mode tensor-matrix product.

Note that transmit and receive array geometries are arbitrary here, and do not need to be uniform. As such, TB also performs the function of array interpolation, as shown in [114]–[119], where the problem of the 2-D transmit array interpolation and beamspace design for monostatic MIMO radar with application to elevation and azimuth estimation was addressed. The 2-D transmit array interpolation was formulated as the minimax convex optimization problem with constraints on array interpolation errors within a spatial sector of interest, while minimizing the transmit power outside the sector. The desired structure of the virtual transmit array (for example, L-shaped array) was then enforced. It allows to benefit from translational invariance property when estimating elevation and azimuth parameters at the receiver. The advantage of the high-dimensional structure inherent in the received signal as explained above (the signal has been folded into a higher-order tensor) permits use of tensor-based ESPRIT methods.

C. Tensor Techniques for TB Design and Parameter Estimation in MIMO Radar with Arrays of Regular Geometries

The DOA estimation bias caused by transmit array interpolation errors, which are unavoidable for the techniques reviewed in the previous subsection, can be partially compensated by building an offline look-up table aimed at decreasing the bias. However, a higher localization accuracy may be achieved if the transmit array has a regular uniform structure. This is because there will be no loss of accuracy arising due to array interpolation, as shown in [120] where the 2-D transmit array was non-adaptively partitioned into a number of subarrays, each contributing a slice in a data tensor at the receiver. Then, TB was adaptively designed for each subarray such that the beampatterns corresponding to each matrix of the TB for each subarray had the exact same magnitude.

For example, if the transmit array is a uniform rectangular array (URA), then the design of TB matrix \mathbf{W} can be performed in two stages. First, a TB matrix $\mathbf{U}_0 = [\mathbf{u}_1, \dots, \mathbf{u}_k]$, with full column rank K , is designed over a spatial sector $\Theta = [\theta_1 \theta_2]$ and $\Phi = [\phi_1 \phi_2]$ using only the first $(P-1)$ rows and $(Q-1)$ columns of the transmit array. Then, a simple transformation is performed on \mathbf{U}_0 to produce TB matrices with identical beampatterns, but which correspond to different subarrays as shown in Fig. 7.

It is trivial to show that a matrix \mathbf{U}'_0 of dimension $PQ \times K$, with an identical beampattern to that of \mathbf{U}_0 , can be constructed by placing zeros in the spots corresponding to the antenna

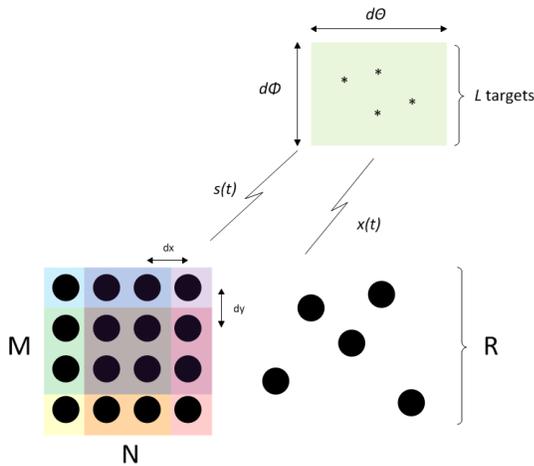

Fig. 7. An example of 2-D uniform rectangular array non-adaptive division to a number of identical subarrays. Different waveforms are sent from different subarrays, but the beampattern shape and RIP between different subarrays is ensured by TB design.

elements which were omitted from the original design of \mathbf{U}_0 . The matrix \mathbf{U}'_0 then denotes a beamforming matrix where K beams are transmitted from the first $P - 1$ rows and $Q - 1$ columns of a transmit array of dimension $P \times Q$. Given the shape of the transmit array, it is simple to show that by shifting the positions of the zeros in \mathbf{U}'_0 , the exact same beampattern can be achieved by subarrays containing the first $P - 1$ rows and last $Q - 1$ columns, the last $P - 1$ rows and the first $Q - 1$ columns, and finally the last $P - 1$ and last $Q - 1$ columns of the transmit array. These three matrices are denoted as \mathbf{U}'_1 , \mathbf{U}'_2 , and \mathbf{U}'_3 , respectively. With these matrices defined, the following statements hold,

$$\begin{aligned} \mathbf{a}^H(\theta, \phi)\mathbf{U}'_0 &= e^{j2\pi d_x \sin \theta \cos \phi} (\mathbf{a}^H(\theta, \phi)\mathbf{U}'_1) \\ &= e^{j2\pi d_y \sin \theta \sin \phi} (\mathbf{a}^H(\theta, \phi)\mathbf{U}'_2) \\ &= e^{j2\pi (d_x \sin \theta \cos \phi + d_y \sin \theta \sin \phi)} (\mathbf{a}^H(\theta, \phi)\mathbf{U}'_3). \end{aligned} \quad (62)$$

The beamforming matrix \mathbf{W} is then defined as $\mathbf{W} \triangleq [\mathbf{U}'_0, \mathbf{U}'_1, \mathbf{U}'_2, \mathbf{U}'_3]$ with an overall dimension of $PQ \times 4K$. Clearly, in the original design problem, the number of resolvable targets K must be no larger than $PQ/4$.

Given the structure (62) imposed on the beamspace matrix \mathbf{W} , we turn our attention to (60). Rewriting the noiseless matrix before vectorization allows to illustrate the structure of \mathbf{W} on DOA estimation. Specifically, we can write

$$\mathbf{B}(\theta, \phi)\boldsymbol{\Sigma}(q)\mathbf{A}^H(\theta, \phi)\mathbf{W} = \mathbf{B}(\theta, \phi)\boldsymbol{\Gamma} \quad (63)$$

where $\boldsymbol{\Gamma} \triangleq \boldsymbol{\Sigma}(q)\mathbf{A}^H(\theta, \phi)\mathbf{W}$ is the source signal matrix of dimension $L \times 4K$. Let $\boldsymbol{\Gamma}_0 = \boldsymbol{\Sigma}(\tau)\mathbf{A}^H\mathbf{U}'_0$ be the source signal matrix corresponding to K beams eliminated from the first $(P - 1)$ rows and $(Q - 1)$ columns of the transmit array. We define matrices $\boldsymbol{\Omega}_i, i \in \{0, 1, 2, 3\}$ as the $L \times L$ diagonal matrices, with the l th diagonal entry of $\boldsymbol{\Omega}_i$ being the complex exponential in (62) which relates $\mathbf{a}^H(\theta, \phi)\mathbf{U}'_0$ to $\mathbf{a}^H(\theta, \phi)\mathbf{U}'_i$. The matrix $\boldsymbol{\Omega}_0$ is obviously the identity matrix. Then, (63)

can be expressed as the following block partitioned matrix

$$\begin{aligned} \mathbf{B}\boldsymbol{\Gamma} &= \mathbf{B} \begin{bmatrix} \boldsymbol{\Omega}_0\boldsymbol{\Gamma}_0 & \boldsymbol{\Omega}_1\boldsymbol{\Gamma}_0 & \boldsymbol{\Omega}_2\boldsymbol{\Gamma}_0 & \boldsymbol{\Omega}_3\boldsymbol{\Gamma}_0 \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{B}\boldsymbol{\Omega}_0 & \mathbf{B}\boldsymbol{\Omega}_1 & \cdots & \mathbf{B}\boldsymbol{\Omega}_3 \end{bmatrix} \text{bdiag}_4(\boldsymbol{\Gamma}_0) \end{aligned} \quad (64)$$

where we drop the dependence of \mathbf{B} on (θ, ϕ) , $\text{bdiag}_m(\cdot)$ takes a single matrix as an argument and creates a block diagonal matrix whose m blocks are equal to its argument. The matrix $\mathbf{B}\boldsymbol{\Omega}_0$ is simply the receiver response matrix to K targets. The virtual receiver response matrices $\mathbf{B}\boldsymbol{\Omega}_1$, $\mathbf{B}\boldsymbol{\Omega}_2$, and $\mathbf{B}\boldsymbol{\Omega}_3$ are exactly the receiver response matrices to K targets, for identical receive arrays that are linearly displaced from the actual receiver by $[d_x, 0]$, $[0, d_y]$, and $[d_x, d_y]$, respectively. The source signal matrix $\boldsymbol{\Gamma}_0$ is a common factor for each. From (64), it is visible that the structure for \mathbf{W} enforces an algebraic structure on \mathbf{Y} which can be exploited by search-free algorithms for DOA estimation, such as, for example, ESPRIT. Moreover, (64) can be viewed as an unfolding of a tensor with each slice to be one of the 4 matrices $\mathbf{B}\boldsymbol{\Omega}_i, i = 0, 1, 2, 3$.

Matrix \mathbf{Y} has dimension $4RK \times Q$ and is obtained by unfolding the corresponding tensor \mathcal{Y} of signal for all Q pulses. After defining the matrix selection operator $\mathbf{F}_i(\cdot)$, which selects the $(iM/4 + 1) - M/4(i + 1)$ rows from an arbitrary matrix with M rows, where $i = 0, 1, 2, 3$, \mathbf{Y} and a new matrix \mathbf{Y}' can be expressed as

$$\mathbf{Y} = \begin{bmatrix} \mathbf{F}_0(\mathbf{Y}) \\ \mathbf{F}_1(\mathbf{Y}) \\ \mathbf{F}_2(\mathbf{Y}) \\ \mathbf{F}_3(\mathbf{Y}) \end{bmatrix}, \quad \mathbf{Y}' = \begin{bmatrix} \mathbf{F}_0(\mathbf{Y}) \\ \mathbf{F}_2(\mathbf{Y}) \\ \mathbf{F}_1(\mathbf{Y}) \\ \mathbf{F}_3(\mathbf{Y}) \end{bmatrix}. \quad (65)$$

Forming the cross correlation matrices $\mathbf{R}_\mathbf{Y} = \mathbf{I}^{-1}\mathbf{Y}\mathbf{Y}^H$ and $\mathbf{R}_{\mathbf{Y}'} = \mathbf{I}^{-1}\mathbf{Y}'\mathbf{Y}'^H$, and performing ESPRIT on both will yield a vector of L phase arguments which are directly proportional to ζ_l and γ_l . Defining a complex number $z_l = \gamma_l + j\zeta_l$, the angle estimates are given by $\phi_l = \arctan(\zeta_l/\gamma_l)$, and $\theta_l = |z_l|$.

The above described structure of the TB matrix \mathbf{W} is just a special case shown in Fig. 7. However, the approach can be generalized to allow a flexible subarray selection, more general transmit array geometries than URA, and more computationally efficient tensor decomposition techniques that use the additional structures in the signal tensor. These and other generalizations have been addressed in recent work [121]. The additional structure in the signal tensor comes from the Vandermonde structure of the factor matrices. The term that was recently coined for decomposition methods of tensors with some additional structures that need to be taken into account and may lead to significant improvement of computational efficiency is CONFAC decomposition [88]. The decomposition methods proposed in [121] belong to this class of tensor decomposition techniques.

Finally, an extension of TB design method for AoA/AoD estimation in bistatic MIMO radar was recently proposed in [122], wherein uniform power distribution across the transmit array elements was achieved via inequality constraints.

D. Tensor Techniques for Slow-Time MIMO Radar

A notifiable disadvantage of MIMO radar is the need for multiple orthogonal waveforms. Indeed, multi-waveform MIMO radar demands several signal generators to transmit orthogonal waveforms, which can be costly and unacceptable especially in such applications as automotive MIMO radar. However, using additional M phase shifters at the transmit array instead of multiple orthogonal waveform generators, the implementation of MIMO radar can be still upgraded easily from a legacy Single-Input Multiple-Output (SIMO) radar, where only one signal generator is used. The associated waveform design approach has been called Doppler division multiple access (DDMA) technique, and the corresponding signal model can also be represented in tensor form [123]. The essence of this *slow-time MIMO radar* framework is to modulate each transmit signal with a unique Doppler shift via pulse-to-pulse phase coding. Under this circumstance, the model in (53) can be modified to represent the received signal of MIMO radar using DDMA technique as

$$\mathbf{Y} = [(\mathbf{A} \diamond \mathbf{B}) \mathbf{C}^T] \odot \mathbf{D} + \mathbf{Z} \quad (66)$$

where $\mathbf{D} \triangleq (\mathbf{I}_M \diamond \mathbf{1}_{N \times M}) \mathbf{P}$, $\mathbf{P} \in \mathbb{C}^{M \times Q}$ is the phase modulation matrix that achieves waveform diversity in Doppler domain, and $\mathbf{1}_{N \times M}$ is a $N \times M$ all-one matrix. It can be observed that matrix \mathbf{D} also represents the PARAFAC decomposition. It is worth noting that the independence of phase modulation matrix and the received signal can be exploited in the context of slow-time MIMO radar. Based on this property, a novel tensor model was designed to improve the target parameter estimation performance in [123]. Moreover, the additional phases on transmit array lead to a cyclically varying transmit beampattern from pulse to pulse, which can be regarded as a special case of TB design.

V. CONCLUSION

In this paper, we presented a comprehensive overview of tensor decompositions in wireless communications and MIMO radar. We provided a description of basic tensor operations and decompositions, thus establishing the preliminaries for advanced application-driven discussions. Within the area of wireless communications, we provided an in-depth description of tensor-based methods for blind symbol recovery and channel parameter estimation, focusing on CDMA, STF, cooperative/relay, MIMO, and mmWave systems. We also reviewed tensor techniques for transmit beamspace design and target parameter estimation in MIMO radar. The presented methods and strategies highlighted the prospects and potential of tensor algebra and decompositions in wireless communications and MIMO radar.

Hongyang Chen (SM'16) received the B.S. and M.S. degrees from Southwest Jiaotong University, Chengdu, China, in 2003 and 2006, respectively, and Ph.D degree from the University of Tokyo, in 2011. From 2004 to 2006, he was a research assistant in Institute of Computing Technology, Chinese Academy of Science. In 2009, he was a visiting researcher in the Adaptive Systems Laboratory at University of California Los Angeles, USA. From 2011 to 2020, he worked as a researcher for Fujitsu Ltd, Japan. Currently, he is a principal investigator/senior

research expert of Zhejiang Lab, China. He has published 90 refereed journal and conference papers in ACM Trans. on Sensor Networks, IEEE Trans. on Signal Processing, IEEE Trans. on Wireless Communications, IEEE MILCOM, IEEE GIOBECOM, IEEE ICC and more and has been granted/filed more than 50 PCT patents. He served as a symposium chair/special session organizer for some flagship conferences, including IEEE PIMRC, IEEE MILCOM, IEEE GLOBECOM, and IEEE ICC. He received the Best Paper Award from IEEE PIMRC'09. He served as the editor for IEEE Trans. on Wireless Communications, and the associate editor for IEEE Communications Letters. He is a leading guest editor for IEEE Journal on Selected Topics of Signal Processing on Tensor decomposition and an associate editor for IEEE Internet of Things Journal. He has been selected as the Distinguished Lecturer of the IEEE Communication Society in 2021–2022. His research interests include IoT, data-driven intelligent networking and systems, machine learning, localization, location-based big data, B5G, and statistical signal processing.

Fauzia Ahmad (F'18) received her Ph.D. degree in electrical engineering from the University of Pennsylvania in 1997. She is an Associate Professor in the Department of Electrical and Computer Engineering, Temple University. Prior to joining Temple University in 2016, she was a Research Professor and the Director of the Radar Imaging Lab at the Center for Advanced Communications, Villanova University. She is a Fellow of IEEE and a Fellow of the International Society of Optical Engineering (SPIE). She is the recipient of the 2017 IEEE Aerospace and

Electronic Systems Society Harry Rowe Mimno Award, the 2016 Institute of Engineering and Technology (IET) Premier Award, and the 2014 IEEE Aerospace and Electronic Systems Society M. Barry Carlton Award. She is the past chair of the IEEE Dennis J. Picard Medal for Radar Technologies and Applications Committee and the 2012–2018 SPIE Compressive Sensing Conferences. She currently chairs the SPIE Big Data Conference series and is a member of the Sensor Array and Multichannel Technical Committee of the IEEE Signal Processing Society, the Computational Imaging Technical Committee of the IEEE Signal Processing Society, a member of the Synthetic Aperture Technical Working Group of the IEEE Signal Processing Society, and a member of the Electrical Cluster of the Franklin Institute Committee on Science and the Arts. She was a member of Radar Systems Panel of the IEEE Aerospace and Electronic Systems Society from 2014–2020. She also serves as an Associate Editor of the IEEE TRANSACTIONS ON COMPUTATIONAL IMAGING and IET RADAR, SONAR, & NAVIGATION. She was an Associate Editor of the IEEE TRANSACTIONS ON SIGNAL PROCESSING from 2014–2018. She has over 250 publications and eight book chapters in the areas of array and statistical signal processing, computational imaging, compressive sensing, and machine learning, with applications in radar, ultrasonics, and satellite navigation.

Sergiy Vorobyov (F'18) received the M.Sc. and Ph.D. degrees in systems and control from Kharkiv National University of Radio Electronics, Kharkiv, Ukraine, in 1994 and 1997, respectively. He is a Fellow of IEEE and Professor with the Department of Signal Processing and Acoustics, Aalto University, Finland. He has been previously with the University of Alberta, Canada as an Assistant, an Associate, and then a Full Professor. Since his graduation, he also held various research and faculty positions with the Kharkiv National University of Radio Electronics,

Ukraine; the Institute of Physical and Chemical Research, Japan; McMaster University, Canada; Duisburg-Essen University and Darmstadt University of Technology, Germany; and the Joint Research Institute between Heriot-Watt University and Edinburgh University, U.K. His research interests include optimization and multi-linear algebra methods in signal processing; statistical and array signal processing; sparse signal processing; estimation and detection theory; sampling theory; and multi-antenna, very large, cooperative, and cognitive systems. Dr. Vorobyov is the recipient of the 2004 IEEE Signal Processing Society Best Paper Award, the 2007 Alberta Ingenuity New Faculty Award, the 2011 Carl Zeiss Award (Germany), the 2012 NSERC Discovery Accelerator Award, and other awards. He has been currently Senior Area Editor for the IEEE SIGNAL PROCESSING LETTERS since 2016. He was an Associate Editor for the IEEE TRANSACTIONS ON SIGNAL PROCESSING in 2006–2010 and the IEEE SIGNAL PROCESSING LETTERS in 2007–2009. He was a member of the Sensor Array and Multi-Channel Signal Processing and Signal Processing for Communications and Networking Technical Committees of the IEEE Signal Processing Society in 2007–2012 and 2010–2016, respectively. He was the Track Chair for Asilomar 2011, Pacific Grove, CA, USA; the Technical Co-Chair for IEEE CAMSAP 2011, Puerto Rico; the Tutorial Chair for ISWCS 2013, Ilmenau, Germany; the Technical Co-Chair for IEEE SAM 2018, Sheffield, U.K.; and the Technical Co-Chair for IEEE CAMSAP 2021, Costa-Rica.

Fatih Porikli (F'14) received his Ph.D. from New York University in 2002. He is a Fellow of IEEE and a Professor in the Research School of Engineering, Australian National University. He is also serving as the Vice President at Futurewei CBG Device Hardware in San Diego. He led the Computer Vision Research Group Leader at NICTA, Australia and managed applied research projects as the Distinguished Research Scientist at Mitsubishi Electric Research Laboratories, Cambridge. He developed satellite imaging solutions at HRL, Malibu CA, and

3D display systems at AT&T Research Laboratories, Middletown, NJ. His research interests include computer vision, deep learning, manifold learning, online learning, and image enhancement with commercial applications in smartphones, AR/VR, autonomous vehicles, video surveillance, defense, and medical systems. He received the R&D 100 Scientist of the Year Award in 2006, won six best paper awards at scientific events, and recognized with six professional prizes at his industrial appointments. He authored more than 300 publications, co-edited two books, and invented 80 US patents. He was the General Chair and Technical Program Chair of the IEEE Winter Conference on Applications of Computer Vision (WACV) in 2014 and 2015, and IEEE Advanced Video and Signal based Surveillance Conference (AVSS) in 2010 and 2012. He has been an Associate Editor of several IEEE and Springer journals for the past 15 years.
